Abstract

The year 2023 marks 60 years since the first pacemaker was implanted in Poland. The number of implantable cardiac electrotherapy devices (CIEDs), including pacemakers, cardioverter-defibrillators, and resynchronization therapy systems, has been systematically increasing in the subsequent decades. It is estimated that nearly 500,000 Poles have an implanted cardiac electrotherapy device, making optimal diagnostic imaging with the use of magnetic resonance imaging (MRI) a clinically and epidemiologically important issue.

MRI has become a gold diagnostic standard in many disease states. In this situation, it is believed that 50-70% of patients who have a cardiac electrotherapy device may have indications for an MRI examination later in life. For many years, an implanted cardiac electrotherapy device was considered a definite contraindication to MRI. However, MRI has become possible in most patients with CIED if certain procedures and precautions are followed.

In these guidelines, we describe the basic rules that should be followed in order to perform a safe MRI examination in patients with different CIEDs.

Despite all the risks and organizational factors described in the text, it seems that for many MRI departments, MRI in patients with CIEDs is achievable and should be implemented immediately. A second important issue is the need for dedicated financial support for these procedures from public health insurance.

Key words: magnetic resonance imaging, cardiac electrography devices, guidelines.

Introduction

In 2023, it has been 60 years since the first pacemaker was implanted in Poland. The first defibrillator was implanted in Poland in 1986, the first cardioverter defibrillator (ICD) with transvenous electrodes was implanted in 1995, and the first resynchronization therapy pacing device was implanted in 1997. The number of implantable cardiac electrotherapy devices (CIEDs), including pacemakers, cardioverter-defibrillators, and resynchronization therapy systems, has been systematically increasing in the subsequent decades. It is estimated that nearly 500,000 Poles have an implanted cardiac electrotherapy device, making optimal diagnostic imaging with the use of magnetic resonance imaging (MRI) a clinically and epidemiologically important issue.

MRI has become a gold diagnostic standard in many disease states. In this situation, it is believed that 50-70% of patients who have a cardiac electrotherapy device may have indications for an MRI examination later in life. For many years, an implanted cardiac electrotherapy device was considered a definite contraindication to MRI. However, MRI has become possible in most patients with CIED if certain procedures and precautions are followed.

In these guidelines, we describe the basic rules that should be followed in order to perform a safe MRI examination in patients with different CIEDs.

Despite all the risks and organizational factors described in the text, it seems that for many MRI departments, MRI in patients with CIEDs is achievable and should be implemented immediately. A second important issue is the need for dedicated financial support for these procedures from public health insurance.
therapy systems, has been systematically increasing; for about 5 years, the number of procedures per 1 million inhabitants has been stable and in line with clinical needs, which is above the European average. Nowadays in Poland, approximately 750 pacemakers and approximately 250 defibrillation devices are implanted (de novo implantation or replacement) per million inhabitants per year, i.e. approximately 38,000 devices per year. It is estimated that nearly 500,000 Poles have an implanted cardiac electrotherapy device, making optimal diagnostic imaging with the use of magnetic resonance imaging (MRI) a clinically and epidemiologically important issue.

MRI is an imaging method that was introduced to medicine in the 1970s. Originally, this method, apart from the high cost, had many limitations, which narrowed the scope of its application. Currently, thanks to the dynamic development of new techniques in MRI, it has been possible to significantly shorten the acquisition time and eliminate most artefacts such as motion artefacts (e.g. respiratory artefacts, artefacts resulting from the work of the heart or pulsating blood flow in arterial vessels). Thanks to this, it became possible to obtain good quality images not only of the central nervous system or the musculoskeletal system but also of the heart, abdominal organs, or mediastinum. Compared to other imaging tests, MRI is a comprehensive method; it enables simultaneous structural (morphological) and functional evaluation, which makes it indispensable in many fields of medicine, such as oncology, neurology, neurosurgery, cardiology, orthopaedics, and gynaecology.

MRI is widely available. This examination is recognized as the gold diagnostic standard in many disease states. In this situation, it is believed that 50-70% of patients who have a cardiac electrotherapy device may have indications for MRI examination later in life.

MRI, compared to computed tomography, is characterised by a slightly lower spatial resolution and a much larger scale of applicable precautions or contraindications to the examination. For many years, these contraindications included patients with an implanted cardiac electrotherapy device. It should be emphasised that at present, as a result of many years of experience, both global and Polish [1-10], confirming the safety of such procedures, MRI is possible in the vast majority of patients with CIED if certain procedures and precautions are followed.

**Principles of performing magnetic resonance imaging examinations in patients with an implanted cardiac electrotherapy device**

When making the decision to refer a patient for an MRI examination, the risk-benefit ratio of this examination should be considered. Regardless of the type of implanted system, when choosing the type of diagnostic test, it is worth taking into account the presence of image artefacts resulting from the presence of a metal implant in the patient’s body. Thoracic, shoulder, and heart tests can contain artifacts that make exam evaluation difficult. However, if it is not possible to choose other diagnostic methods, a magnetic resonance scan can be performed or attempted if it does not pose a high risk to the patient.

During an MRI scan in a patient with an implanted electrotherapy system an increase of lead temperature (especially at the tips), inhibition of the pacing, change in pacing mode, loss of set parameters, software, or reset of the device (to factory or rescue pacing parameters) may occur. In the case of a patient with an implantable cardioverter-defibrillator entering the gantry without first deactivating the device, inadequate shock devices may occur.

In light of the current state of knowledge, patients with epicardial leads are at highest risk of performing this test, due to the consequences of heating the system components (leads placed extravascularly). MRI in patients with abandoned, inactive electrodes is also high risk. In these patients, examination should be performed only with absolute vital indications, while ensuring the best possible
During imaging, the patient must have ECG and oxygen saturation continuously monitored. The laboratory should be equipped with a defibrillator with the function of transcutaneous pacing.

The technical conditions for conducting the tests (in terms of magnetic field inductance limits, specific absorption rate values, and gradient growth rates or possible exclusion areas) are available on the websites of the manufacturers of cardiac implantable devices (they vary depending on the manufacturer, type and model of leads, and the model of the pulse generator).

From a technical point of view, such an examination is possible in any hospital where, as well as a MRI laboratory, there is a laboratory for the control of implantable devices.

**Organisation of MRI examinations**

Undoubtedly, conducting such an examination safely requires increased workload, appropriate equipment, and the involvement of additional personnel. In addition to the standard team of the MRI laboratory, electrophysiological consultation and supervision is necessary, a team consisting of a cardiologist and a cardiac technician or a nurse experienced in programming devices (depending on possessed powers and competences), in order to conduct qualifications to perform the test, follow-up of the device before and after the test, adjust the pacing parameters of the device for the duration of the test, and supervise the recording of the patient's ECG and saturation during the test [13].

In some cases, the cost of performing such an examination may also be increased by the costs of transporting...
the patient between the centre where the patient is hospitalized and the hospital in which the device will be checked and the imaging examination will be performed. Taking into account the factors described above, it seems necessary to provide special funding for MRI in patients with an implanted cardiac electrotherapy device by the National Health Fund.

Despite all the risk and organisational factors described above, it seems that for many hospitals, the organization and development of internal procedures to carry out such tests is achievable and should be implemented immediately. A second important issue is the need for dedicated financial support for these procedures from public health insurance.
